1. Introduction

1.1 Document Purpose

This Deployment Plan and Production Architecture document serves as the authoritative technical reference for deploying StockWise, an AI-powered inventory optimization platform developed by Team Rojak (ID 109) for UMHackathon 2026. The document addresses three critical evaluation criteria from the judging rubric: Technical Stack and Scalability (7%), CI/CD Pipeline and Automation (7%), and Integration Security and Credential Management (6%), which collectively account for 20% of the final round score. Each section provides detailed technical specifications, architectural decisions, and implementation strategies that demonstrate production-readiness and systematic engineering discipline. The deployment strategy outlined herein ensures that StockWise can transition from a hackathon prototype to a reliable, scalable production system serving Malaysian SMEs.

1.2 Scope and Objectives

The scope of this deployment plan encompasses the full technical lifecycle from source code to production runtime, covering infrastructure provisioning, build automation, continuous integration, deployment orchestration, and security hardening. The primary objectives are threefold: first, to establish a reproducible deployment process that eliminates manual configuration errors and ensures consistent environments across development, staging, and production; second, to define scalability strategies that allow StockWise to grow from a single-server MVP to a multi-instance production platform handling hundreds of concurrent users; and third, to implement comprehensive security measures that protect sensitive data, API credentials, and AI integration points from unauthorized access and malicious exploitation.

1.3 Live Deployment Reference

The StockWise application is currently deployed and accessible at the following URL for live demonstration and evaluation:

Live Deployment URL	https://c1ye938tnkg0-deploy.space.z.ai/
Repository	https://github.com/teohweibin/Team_Rojak.git
Runtime	Bun / Next.js 16 Standalone

Team Name & ID	109 - Team Rojak

2. Technical Stack and Scalability

2.1 Architecture Overview

StockWise is designed as a monolithic full-stack web application built on the Next.js 16 framework, which provides both the frontend presentation layer and the server-side API routes within a single unified codebase. This architectural decision was deliberately made to maximize development velocity during the hackathon timeline while maintaining a clear separation of concerns between client-side UI rendering and server-side business logic. The application follows the Next.js App Router pattern, where each functional module is implemented as a self-contained route with its own page component, data-fetching hooks, and associated API endpoints.

The system employs a single-page application (SPA) architecture where all eight functional modules (Dashboard, Inventory, Products and Suppliers, Sales Velocity, Exchange Rates, Market News, AI Recommendations, and Strategy Validation) are accessible through a unified dashboard interface. Client-side state management controls which module is displayed to the user, providing a seamless, app-like experience without page reloads. This is particularly important for maintaining context during AI-powered analysis workflows, where users need consistent access to their data while waiting for GLM API responses that may take up to 15 seconds to complete.

The database layer uses SQLite managed through Prisma ORM, which provides type-safe database access, automatic schema migrations, and a comprehensive seed script (prisma/seed.ts) for populating demo data. The AI integration layer uses the z-ai-web-dev-sdk to communicate with Z AI GLM, encapsulating all AI logic within dedicated API route handlers to keep API keys secure and reduce the attack surface. The production build outputs a standalone Next.js server that runs on the Bun JavaScript runtime for optimal startup performance and lower memory consumption compared to the standard Node.js runtime.

2.2 Technology Stack Detail

The technology stack for StockWise was carefully selected to maximize development velocity during the hackathon while ensuring a robust, maintainable, and scalable codebase. The following table provides a comprehensive breakdown of every technology used across each layer of the application, along with the

specific version, purpose, and scalability characteristics that informed the selection decision.

Layer	Technology	Version	Purpose	Scalability Notes
Frontend	Next.js (App Router)	16	Full-stack React framework with SSR, API routes, and file-based routing	Supports incremental static regeneration; edge runtime available for global CDN deployment
Frontend	React	19	UI component library with hooks for state management and server components	Concurrent features enable non-blocking rendering for heavy data pages
Frontend	Tailwind CSS	4	Utility-first CSS framework with dark theme and responsive design	Zero-runtime overhead; purged CSS reduces bundle size for fast page loads
Frontend	shadcn/ui	Latest	Pre-built, accessible UI component library	Tree-shakeable; components imported individually reduce bundle size
Frontend	Recharts	Latest	Data visualization for dashboard charts	Canvas-based rendering; handles thousands of data points efficiently
Frontend	TanStack Query	5	Server state management for data fetching, caching, and refetching	Configurable stale times reduce redundant API calls by 60-80%
Backend	Next.js API Routes	16	Server-side REST API endpoints for all data operations	Route handlers support streaming for long-running AI requests
Backend	Prisma ORM	6	Type-safe database client with schema definitions and migrations	Connection pooling for PostgreSQL migration; migration system for schema versioning
AI Engine	Z AI GLM (z-ai-web-dev-sdk)	Latest	Core AI reasoning engine via ILMU API for recommendations and simulation	Token-efficient prompting at ~2,000 tokens per call; structured JSON output for reliable parsing

Database	SQLite (better-sqlite3)	3.x	Embedded relational database for zero-configuration persistence	WAL mode for read concurrency; migration path to PostgreSQL for production scale
Deployment	Bun Runtime	Latest	High-performance JavaScript runtime for production build execution	2-4x faster cold starts than Node.js; lower memory footprint enables denser server utilization
Validation	Zod	3	Schema validation for all API input parameters and request bodies	Compile-time type inference; zero-runtime overhead for validation schemas

Table 1: Complete Technology Stack with Scalability Character

2.3 Database Schema and Data Architecture

The StockWise database schema consists of seven interconnected models designed through Prisma ORM, enforcing referential integrity through foreign key constraints and including appropriate indexes for query performance optimization. The Supplier model tracks supplier metadata including country of origin and primary trading currency, which is essential for the AI recommendation engine to calculate procurement costs in MYR and factor exchange rate exposure. The Product model serves as the core product catalog, with each product linked to a single supplier through a foreign key relationship. Critical fields include reorderPoint and leadTimeDays, which are direct inputs for AI recommendation generation and days-of-cover calculations.

The Inventory model maintains a one-to-one relationship with Product through a unique constraint on productId, tracking current stock quantities that drive status classification (Critical when quantity is at or below 25% of reorder point, Low when at or below the reorder point, and Healthy when above threshold). The Sale model records individual transactions with automatic total computation, aggregated over 30-day windows for sales velocity metrics. The Recommendation model stores AI-generated insights with full reasoning chains and news references as JSON strings, while the InventoryMovement model provides a complete audit trail for all stock adjustments. Finally, the ExchangeRate model supports multi-currency tracking for USD/MYR, EUR/MYR, and CNY/MYR conversion rates that feed into the AI analysis pipeline.

2.4 Scalability Analysis and Strategy

The current MVP architecture is optimized for the hackathon context: single-server deployment, SQLite database, and synchronous AI request-response patterns. However, the system has been designed with clear migration paths to support production-scale workloads. The scalability strategy follows a phased approach, where each phase addresses a specific bottleneck identified through load testing and performance profiling. The three-phase plan ensures that scaling investments are proportional to actual user demand, avoiding premature optimization while maintaining a clear roadmap for growth.

2.4.1 Phase 1: Database Migration (Horizontal Read Scaling)

The most critical scalability bottleneck in the current architecture is SQLite, which operates as a file-based database with limited concurrent write capabilities. The migration strategy to PostgreSQL is designed to be non-disruptive, leveraging Prisma ORM's database-agnostic abstraction layer. Since all database interactions are mediated through Prisma Client with typed queries and schema definitions, the migration requires only a configuration change in the database connection URL and execution of Prisma Migrate to generate the PostgreSQL-specific schema. PostgreSQL provides superior concurrent write handling through MVCC (Multi-Version Concurrency Control), connection pooling via PgBouncer, and read replication for horizontally scaling read queries across multiple database instances. This migration

enables the system to handle hundreds of concurrent users with sub-100ms query response times.

2.4.2 Phase 2: Caching Layer (AI Response Optimization)

AI recommendation generation is the most resource-intensive operation in the system, consuming approximately 2,000 tokens per call and requiring 5-15 seconds of processing time. The introduction of a Redis caching layer addresses both performance and cost optimization. Cache entries are keyed by a hash of the underlying data state (inventory levels, sales aggregates, exchange rates, and news articles), ensuring that cached recommendations are invalidated only when the underlying data changes. Based on typical usage patterns where the same inventory state persists for 30-60 minutes between updates, this caching strategy is projected to reduce AI API costs by 60-80% while improving response times for repeat queries from over 8 seconds to under 100 milliseconds. The cache uses a TTL (Time-To-Live) of 30 minutes as a secondary invalidation mechanism to prevent stale recommendations.

2.4.3 Phase 3: Multi-Instance Deployment (Horizontal Compute Scaling)

For enterprise-scale deployments serving 500 or more concurrent users, the system transitions from a single-server monolith to a horizontally scaled multi-instance architecture. This involves deploying multiple Next.js server instances behind a load balancer (Nginx or cloud-native alternatives such as AWS ALB), with sticky sessions for AI generation requests to prevent mid-request routing changes. The PostgreSQL database serves as the single source of truth for all instances, eliminating data consistency concerns. Static assets (Next.js built JS/CSS bundles, images, and fonts) are served through a CDN (CloudFront or Cloudflare) to reduce origin server load and improve global latency. This architecture supports auto-scaling based on CPU utilization and request queue depth, automatically adding or removing server instances in response to traffic patterns. The combination of CDN caching, Redis caching, and database connection pooling ensures that each additional server instance provides near-linear throughput improvement.

Phase	Changes	Capacity Target	Estimated Effort
Phase 1	SQLite to PostgreSQL via Prisma migration; add PgBouncer connection pool	50-100 concurrent users	1-2 days
Phase 2	Add Redis caching for AI responses with data-state-keyed invalidation	200-500 concurrent users	2-3 days

Phase 3	Multi-instance deployment with load balancer, CDN for static assets, auto-scaling	500+ concurrent users	3-5 days

Table 2: Phased Scalability Roadmap

3. CI/CD Pipeline and Automation

3.1 Build Process

The StockWise build process follows a standardized pipeline that transforms source code into a production-ready standalone deployment artifact. The build process is initiated through Next.js's built-in build system, which performs TypeScript compilation, module bundling, tree-shaking of unused code, CSS purging of unused Tailwind styles, and static asset optimization. The output is a standalone build directory that contains the complete application, including the server runtime, all API route handlers, and optimized frontend assets, requiring no external Node.js dependencies at runtime. This standalone build is then executed using the Bun runtime, which provides faster startup times and lower memory consumption compared to the standard Node.js runtime.

3.2 Version Control Workflow

The project uses Git for version control with a structured branching strategy designed to maintain code quality while enabling parallel development. The main branch serves as the stable release branch, where all code has passed integration tests and is ready for deployment. Feature branches are created from main for each new feature or bug fix, following the naming convention feature/description or fix/description. All changes undergo code review through pull requests before merging to main, ensuring that at least two team members have reviewed the code changes for correctness, consistency, and adherence to project conventions. The Git repository is hosted on GitHub at https://github.com/teohweibin/Team_Rojak.git, and all commit messages follow the Conventional Commits specification for automated changelog generation and semantic versioning

3.3 Automated Testing Pipeline

The testing pipeline for StockWise operates across three levels: unit testing for individual functions and API route handlers, integration testing for full-stack data flow verification, and end-to-end testing for complete user workflow validation. Unit tests are executed using manual testing via curl commands and Postman collections, where each API endpoint is tested independently with predefined request payloads and expected response schemas. The isolation strategy uses a mock database populated with controlled test data via the Prisma seed script, ensuring deterministic test outcomes with known product configurations, predetermined sales figures, and fixed exchange rates.

Integration tests verify the complete data flow chain from frontend UI components through Next.js API routes, Prisma ORM, and SQLite database. These tests use real database calls through the Prisma client and real AI API calls to Z AI GLM for critical paths (recommendation generation and strategy simulation). The pass criteria require correct HTTP status codes (200 for success, 400 for validation errors, 500 for server errors), valid

JSON response structures matching documented API contracts, and all required fields present and correctly typed. The overall pass rate threshold is set at 80%, with a 100% pass rate required for critical test cases including AI recommendations generation and inventory status calculation

3.4 Deployment Pipeline

The deployment pipeline transforms the validated build artifact into a running production instance through a structured multi-step process. The pipeline begins with a pre-deployment checklist verification, ensuring that all integration thresholds have been met: zero build errors from the next build command, zero linting errors from next lint, all API endpoints returning expected status codes, and the Prisma seed script executing successfully. Once these checks pass, the deployment proceeds through environment configuration, where production environment variables (Z AI API keys, database connection strings, rate limit configurations) are loaded from secure environment files that are never committed to version control.

The deployment execution follows a blue-green deployment strategy to minimize downtime and enable instant rollback. The current production instance continues serving traffic while the new version is deployed to a parallel environment. Once the new instance passes health checks (API endpoint verification and database connectivity test), traffic is switched to the new instance through a DNS or proxy configuration change. The previous instance remains available for immediate rollback if any issues are detected in the first 15 minutes of the new deployment. The entire deployment process is designed to complete within 5 minutes, with traffic switch-over occurring in under 30 seconds

3.5 CI/CD Release Thresholds

The following quantitative thresholds serve as quality gates that must be satisfied before the application can proceed through the build, test, and deployment pipeline. These thresholds have been defined in the QATD and are enforced as manual checkpoints during the development process. They represent the minimum quality standards required for production deployment, and any failure to meet these thresholds blocks the deployment pipeline until the issue is resolved.

Gate	Requirement	Actual Result	Status
Build	Zero build errors from next build	next build completes with zero errors and zero warnings	Passed
ESLint	Zero linting errors from next lint	ESLint reports zero errors across all source files	Passed
API Health	All endpoints return 200 (or appropriate code)	All 11 API endpoints return expected status codes	Passed
Database	Prisma seed completes without error	seed.ts creates all products, suppliers, sales, rates	Passed
Regression	Minimum 80% of test cases must pass	85% overall pass rate achieved across all test types	Passed
AI Output	Minimum 80% valid JSON output from AI	83% of AI prompt variations produce valid, parseable JSON	Passed
Performance	AI API response under 5,000ms	Average 3,200ms; maximum observed 4,500ms	Passed

Table 3: CI/CD Release Thresholds and Actual Results

3.6 Rollback Strategy

The rollback strategy ensures that the system can be quickly restored to a known-good state in the event of deployment failures or post-deployment issues. The deployment script maintains a history of the previous stable build artifacts, allowing instant rollback by redeploying the previous version. Additionally, all database schema changes are managed through Prisma Migrate, which provides version-controlled rollback capabilities for the data layer. If a critical issue is detected within the first 15 minutes of deployment, the rollback procedure executes within 2 minutes by switching traffic back to the previous instance and reverting any database migrations that were applied as part of the failed deployment. The rollback process has been tested and verified during development, ensuring reliable recovery even under stress conditions.

4. Integration Security and Credential Management

4.1 Security Architecture Overview

StockWise implements a defense-in-depth security architecture that protects the system at multiple layers: network, application, data, and AI integration. The fundamental security principle is that sensitive operations, including database queries, AI API calls, and credential access, are executed exclusively on the server side through Next.js API routes. This server-side execution model ensures that API keys, database connection strings, and AI credentials are never exposed to the client-side code bundle, which could be inspected or decompiled by end users. The application follows the principle of least privilege, where each component has only the minimum permissions required for its function, and all external communications are encrypted using TLS/HTTPS.

4.2 API Key and Credential Management

The Z AI GLM API key is the most critical credential in the StockWise system, as it provides access to the AI reasoning engine that generates inventory recommendations and strategy simulations. The API key is managed through a multi-layer protection strategy. At the storage level, the API key is stored in a
.env.local file within the project root directory, which is listed in the .gitignore file to prevent accidental version control commits. The .env.local file is excluded from Git through explicit patterns in both the root .gitignore and any nested .gitignore files, and the repository history has been verified to contain no instances of the API key or any other sensitive credentials.

At the application level, the API key is accessed through the z-ai-web-dev-sdk's ZAI.create() factory method, which reads the key from the process environment (process.env). The SDK instance is created within the API route handler scope, ensuring that the key exists only in server-side memory and is never serialized, logged, or

transmitted to the client. Environment variable validation occurs at application startup, where the system checks for the presence and format of required environment variables before accepting any requests. If the API key is missing or malformed, the application fails to start with a clear error message, preventing deployment of an improperly configured instance. This "fail fast" approach ensures that security misconfigurations are caught before reaching production rather than manifesting as runtime errors.

4.3 Environment Variable Strategy

StockWise follows the twelve-factor app methodology for configuration management, storing all environment-specific settings as environment variables rather than hardcoded values in the source code. The environment variable strategy distinguishes between non-sensitive configuration (which may be committed to version control for convenience) and sensitive credentials (which are strictly excluded from version control). Non-sensitive variables include NEXT_PUBLIC_APP_NAME, NEXT_PUBLIC_DEFAULT_CURRENCY, and PORT, which define application behavior without posing security risks. Sensitive variables include ZAI_API_KEY, DATABASE_URL, and any future authentication secrets, which are stored exclusively in .env.local files on the deployment server.

Variable	Classification	Storage	Access Pattern
ZAI_API_KEY	Secret	.env.local (gitignored)	Server-side only via z-ai-web-dev-sdk
DATABASE_URL	Secret	.env.local (gitignored)	Server-side only via Prisma Client
PORT	Non-sensitive	.env or default (3000)	Server-side only
NEXT_PUBLIC_APP_NAME	Non-sensitive	.env (committable)	Client and server (prefixed NEXT_PUBLIC_)
RATE_LIMIT_MAX	Non-sensitive	.env or default (10/hr)	Server-side only

Table 4: Environment Variable Classification and Management Strategy

4.4 Input Validation and Data Sanitization

All user input to StockWise is validated at the API route level using Zod schema definitions before processing. Zod provides compile-time type inference and runtime validation, ensuring that every API endpoint receives data in the expected format. The validation strategy covers several attack vectors. SQL injection is prevented through Prisma ORM's parameterized query system, where all database queries use parameter binding rather than string concatenation, making SQL injection impossible even if user input contains malicious SQL fragments. Cross-Site Scripting (XSS) is mitigated by

React's built-in HTML escaping, which automatically sanitizes user-generated content before rendering, and by explicit sanitization of AI-generated text before display.

For inventory adjustment operations, the system validates that quantity values are positive numbers, rejecting negative quantities or non-numeric values with descriptive error messages. Product names and descriptions are validated for length and character set constraints to prevent buffer overflow or encoding-based attacks. Exchange rate values are validated as positive floating-point numbers within reasonable ranges (between 0.01 and 100.0), preventing unrealistic values that could corrupt AI recommendation calculations. All API responses use consistent error formatting with appropriate HTTP status codes: 400 for validation errors (with field-specific error messages), 404 for resource not found, 429 for rate limit exceeded, and 500 for unexpected server errors. Error responses never expose internal system details, stack traces, or database schema information to the client.

4.5 Rate Limiting Implementation

Rate limiting is implemented as a critical security and cost management mechanism for AI-powered endpoints. The recommendation generation endpoint (POST /api/recommendations/generate) is limited to a maximum of 3 requests per minute, while the strategy simulation endpoint (POST /api/simulate) is limited to 10 requests per minute. The rate limiting is enforced using an in-memory sliding window counter that tracks request timestamps per endpoint. When a request exceeds the rate limit, the API responds with HTTP 429 (Too Many Requests) status code and a descriptive error message: "Rate limit exceeded. Please try again in a few seconds." The system remains fully responsive during rate limiting, and no database corruption occurs from rejected requests. After the cooldown period expires, subsequent requests succeed normally.

The rate limiting strategy addresses multiple concerns. First, it prevents accidental or malicious overuse of the Z AI GLM API, which consumes tokens (and therefore incurs costs) for each request. At approximately 2,000 tokens per recommendation call, unlimited usage could quickly exhaust API budgets. Second, it protects the server from being overwhelmed by burst traffic patterns, ensuring that legitimate users receive responsive service. Third, it provides a natural mechanism for upgrading to paid tiers in the business model, where higher rate limits are a feature of premium subscriptions. The rate limiting implementation has been tested under adversarial conditions, including 5 concurrent requests within a 2-second window, and correctly enforced the limit while maintaining system stability.

4.6 AI Output Security and Hallucination Mitigation

AI-generated content introduces a unique security concern that is distinct from traditional web application vulnerabilities. The StockWise system implements six layers of hallucination mitigation to ensure that AI outputs are reliable, grounded in real data, and safe for business decision-making. These layers address both the technical risk of fabricated data and the human trust factor that is critical for user adoption in a business-critical domain like inventory management.

Layer	Mechanism	Description
1	News Reference Validation	All news reference indices in AI recommendations are validated against known bounds (1-6). Indices outside this range are silently discarded, preventing fabricated news references from being displayed to users.
2	SKU Cross-Referencing	Recommended product SKUs are verified against the database to ensure the AI does not recommend actions for non-existent products. Invalid SKUs cause the recommendation to be flagged or discarded.
3	Savings Value Capping	Monetary savings values are validated against reasonable ranges. Values exceeding 10x the product inventory value or below zero are flagged as potential hallucinations and capped.
4	Structured JSON Schema	Enforced JSON output format constrains the AI response to specific fields with defined types, significantly reducing free-form hallucination risk.
5	Parse Failure Fallback	If JSON.parse fails on the AI response, the system returns a clear error message instead of displaying raw content. The raw response is logged for debugging but never shown to users.
6	Human-in-the-Loop Design	All recommendations include full reasoning chains and news references, allowing users to evaluate the AI logic before acting. The system is a decision-support tool, not an autonomous agent.

Table 5: Six-Layer AI Hallucination Mitigation Strategy

4.7 Snapshot Architecture for Data Consistency

A critical architectural decision in StockWise is the implementation of a "Snapshot Architecture" for AI recommendation generation. Because the Z AI API takes 5 to 15 seconds to process a prompt, there is a risk that a user might update an inventory level or exchange rate while the AI is analyzing the old data, resulting in a recommendation based

on a stale database state. To address this, the moment the user clicks "Generate New Insights," the system queries the SQLite database and freezes that exact data state in memory. The Z AI prompt is constructed entirely from this frozen snapshot, ensuring logical consistency between the AI advice and the data it claims to be based on. Any user changes made during the API wait time are ignored for that specific generation cycle. This approach guarantees that the reasoning chain displayed to the user accurately reflects the data that was analyzed, building trust in the AI system and preventing confusion from mismatched recommendations.

4.8 Security Best Practices and Hardening

Beyond the specific mechanisms described above, StockWise adheres to several security best practices that contribute to overall system hardening. All API endpoints use HTTPS exclusively, with no HTTP fallback, ensuring that all data in transit is encrypted. The Content Security Policy (CSP) headers are configured to restrict resource loading to approved domains, preventing cross-site scripting and data injection attacks. The HTTP Strict Transport Security (HSTS) header is set to enforce HTTPS connections and prevent protocol downgrade attacks. Server-side logging captures all HTTP 4xx and 5xx responses with request details and stack traces for post-incident analysis, while ensuring that no sensitive data (API keys, user input, or AI responses) is logged.
The repository hygiene practices include regular dependency audits using npm audit to identify known vulnerabilities in third-party packages, pinned dependency versions in package.json to prevent unexpected breaking changes, and a .gitignore configuration that excludes all sensitive files including .env.local, database files, and build artifacts. The system does not store any Personally Identifiable Information (PII) or sensitive financial data; only operational inventory data (product names, quantities, prices) is stored, and no external financial system integration exists that could expose additional attack surfaces. The next-auth integration is prepared but not activated in the MVP, providing a ready-to-enable authentication layer for future multi-user deployments.

5. Monitoring and Incident Response

5.1 Production Monitoring Strategy

The monitoring approach for StockWise is designed for the current MVP environment and focuses on basic observability through server-side logging. Server logs are captured using the tee command to simultaneously output to the console and append to timestamped log files, enabling both real-time monitoring during development and post-incident analysis. Key monitoring areas include: API error tracking, where all HTTP 4xx and 5xx responses are logged with request details and stack traces; AI service response monitoring, which tracks GLM API call durations, success rates, and response quality; rate limit enforcement logging, which records events when users approach or exceed the configured thresholds;

and database query performance monitoring, which identifies slow queries that may need optimization.

For production deployment, the team recommends upgrading to structured logging with JSON-formatted log entries for machine-parseable analysis, implementing health check endpoints (/api/health) for uptime monitoring services such as UptimeRobot or Pingdom, and potentially integrating with observability platforms such as Grafana or Datadog for real-time dashboards and alerting capabilities. Application Performance Monitoring (APM) tools would provide detailed insights into request latency distributions, memory usage patterns, and CPU utilization trends, enabling proactive identification of performance degradation before it impacts users. The monitoring strategy follows the principle that you cannot improve what you cannot measure, and every production issue should be traceable through logs to its root cause.

5.2 Incident Response Protocol

In the event of a critical failure or unexpected behavior, the incident response protocol follows a structured four-phase approach: Detection, Assessment, Resolution, and Prevention. Detection occurs through monitoring alerts (health check failures, error rate spikes, or user-reported issues). Assessment involves reviewing logs to identify the root cause, determining the severity (P0 for system crash or data loss, P1 for broken core feature, P2 for degraded performance), and estimating the blast radius. Resolution follows the rollback strategy described in Section 3.6, where the system is restored to the last known-good state within 2 minutes for P0 issues. Prevention completes the cycle by documenting the root cause analysis, implementing fixes, and adding test cases to prevent recurrence. The deployment strategy includes the ability to revert to a previous stable build using the deployment script, and all database schema changes are managed through Prisma Migrate with version-controlled rollback capabilities.

6. Conclusion and Production Readiness Assessment

This Deployment Plan and Production Architecture document demonstrates that StockWise has been developed with systematic engineering discipline that extends beyond feature implementation to encompass the full software delivery lifecycle. The technical stack selection balances development velocity with production readiness, leveraging modern frameworks (Next.js 16, React 19, Prisma ORM) that provide built-in scalability paths. The three-phase scalability roadmap provides a clear, cost-proportional path from the current single-server MVP to enterprise-scale multi-instance deployment, with each phase addressing a specific bottleneck and delivering measurable capacity improvements.

The CI/CD pipeline, while currently manual, follows established software engineering best practices with clearly defined quality gates, release thresholds, and rollback mechanisms. All seven release thresholds have been verified and passed, demonstrating that the codebase meets the required standards for build integrity, code quality, API functionality, test coverage, AI output reliability, and performance. The security architecture implements

defense-in-depth principles with six layers of AI hallucination mitigation, comprehensive input validation through Zod schemas, rate limiting for cost and abuse prevention, and rigorous credential management through environment variables with git-ignored storage. The system is live and accessible at the deployment URL for demonstration and evaluation.
